

Bio

My name is Ashlynn Steeves, I am a fourth year Biomedical Engineering student from the University of Victoria. I am working with the CFIA from September to December 2019 to complete my fourth and final co-op placement. During this placement I will be participating in the development of predictive genomics software, and the analyses of genome sequence data in support of the national brucellosis program.

Background

Brucellosis is a disease caused by several species of bacteria within the *Brucella* genus. It is chronic, contagious and a zoonotic disease, meaning it can spread from animals to humans. There are various types of brucellosis, including [1]:

- *Brucella abortus*, which primarily affects cattle, bison and elk
- *Brucella suis*, which primarily affects swine
- *Brucella melitensis*, which primarily affects goats and sheep

In Canada, brucellosis is a disease that is readily controlled through federal surveillance and eradication programs. However, the threat posed by *Brucella* infecting domestic animals has not been eradicated. Its presence in bison in northern Alberta continues to pose significant risk to expansion of livestock (cattle and bison) operations and re-establishment in wood bison in the area. *Brucella* is also a concern in domestic cattle as an outbreak can result in significant economic losses [2]. Furthermore, it is a potential human health risk, as humans can become infected by all types of brucellosis, resulting in a disease called undulant fever.

Previous research projects have enabled implementation of standard PCR tools such as the Bruce-ladder technique for identification of many *Brucella* species; however, not all species have suitable diagnostic markers, and biovars within species also suffer from a lack of identified differential genomic markers [3].

In this study, a large-scale comparative whole genome sequence data analysis will seek unique markers for identification of *Brucella* at the species and biovar levels. This information will assist in the development of new more efficient molecular tools for isolate identification. Such tools will further improve the surveillance and import control program of the CFIA [3].

Implementation

This project uses publicly available *Brucella* data from NCBI GenBank (711 sequences), with the potential addition of sequences generated as part of the

national brucellosis program. The data is pre-processed to ensure it is of satisfactory quality and is properly labeled.

Using the k-mer counting approach, specifically the kSNP3 tool, the population structure of the genomes was identified. This structure both validates the proper labeling of data and provides valuable insight into the relationships between genomes from the *Brucella* species.

By training machine learning models such as set covering machines, random forests, and artificial neural networks we hope to identify predictive markers for the differentiation of *Brucella* at the species and biovar level.

Following the identification of these markers a visual representation will be generated to effectively communicate the distribution of markers across species.

Expected results

As a result of the work to be completed this term we expect to obtain a series of markers that can be used to identify the different species of *Brucella*. Such markers could be the persence of absense of a genomic region or single nucleotide varriants in shared genes. Ideally these markers will be implemented in downstream tests such as real-time PCR diagnostics, and useful as predictive markers in metagenomics studies.
